Victorian Rock Lobster Fishery

Stock Assessment Report for the 2023/24 Season

1. EXECUTIVE SUMMARY

Overview

This report details the results of the 2023/24 stock assessment for the Victorian Rock Lobster Fishery. The assessment includes analysis of the fishery against the stock performance indicators and limit reference points set out in the new management plan (VFA 2024). A key principle in the management plan is to ensure that the stocks rebuild in order to meet the plan's objectives and optimise benefits for all users. The management plan includes a harvest strategy that uses standardised catch rate, egg production levels, pre-recruit abundance and a set of decision rules to determine the total allowable commercial catch (TACC) for each zone in the fishery. This 2023/24 assessment applies the new harvest strategy to the zones to provide a basis for the TACC setting process for 2025/26.

Western Zone Rock Lobster Fishery

The TACC for the Western Zone in 2023/24 TACC was to 242t, which was a reduction from 246 tonnes (t) in 2022/23 to align with the rebuilding plan under the new harvest strategy. The modelling underpinning the new harvest strategy was updated in early 2024 to incorporate new recruitment information. The resulting change to the CPUE-TACC tables resulted in an increase to 245t. The new harvest strategy will continue to pursue stock rebuilding and resultant increasing catch rates.

Overall, the stock indicators in the Western Zone continue to show improvement. The standardised catch per unit effort (CPUE) improved from 0.74kg/pot-lift in 2021/22 to 0.78 in 2022/23 and remained at 0.78 in 2023/24. The pre-recruit index (PRI) indicates the abundance of undersize lobsters. This reached a record low in 2015/16. Despite increasing slowly, it remained close to this record low over the subsequent three years. In the last four years the PRI has been at a level marginally above the threshold level (1.82 in 2023/24 compared with the 1.67 undersize / pot-lift threshold level).

Egg production has been declining slightly the last three years. In 2023/24 egg production was at 22.4% which is above the 20% limit reference point. A new alternative method used for calculating egg production confirms that egg production is above the 20% reference point with near certainty.

Biomass had been increasing slowly from a recent low in 2008/09, however slightly decreased the last four years to 851t in 2023/24. Recruitment has been below the long-term average since 2007/08. The pre recruit index has been at a similar level in the last three years, exhibiting a slight downward trend, which is above the new threshold level. This threshold level has been reduced in the new harvest strategy as the harvest strategy places greater emphasis on using conservative TACs to manage the fishery and relies less on recruitment of pre-recruits to support catches in the near future.

Eastern Zone Rock Lobster Fishery

In 2021/22, the Eastern Zone TACC was reduced to 32t which was retained in 2022/23 due to ongoing declines in CPUE. The Eastern Zone TACC in 2023/24 was reduced to 21t following consideration of the extended history of stock issues in the zone and additional consideration to aligning with the strategic direction of the new harvest strategy. As noted in the 2023/24 quota order, the new harvest strategy aims to immediately strengthen stock rebuilding in pursuit of higher catch rates and improved efficiency.

Over the last three years nominal CPUE has continued to decline, however more positively, the standardised CPUE which provides a better indicator for stock status has been increasing, rising from the recent low of from 0.36 kg/pot-lift in 2019/20 to 0.49kg/pot-lift in 2022/23 and a substantial increase to 0.60kg/pot-lift in 2023/24. This positive sign must be treated with some caution as the reduced size of the fishery means there is less data for calculating the CPUE time series and the reliability of this is reduced.

The pre-recruit index (PRI) reached a low of 0.08 undersize / pot-lift in 2018/19. In the following three years substantial increases were observed to a level exceeding the PRI threshold. However, in 2022/23 PRI fell to 0.09 undersize / pot-lift and declined further to a new record low of 0.02 undersize / pot-lift in 2023/24.

Egg production fell from a recent high of 27.2% in 2013/14 to 22.9% in 2021/22. As a cost saving measure, the stock assessment model was not conducted in 2023/24 hence this number was not updated. However a weight of evidence approach outlined here and evaluation against a CPUE based proxy indicates that it is highly likely to remain above the 20% limit reference point.

2. INTRODUCTION

The *Victorian Rock Lobster Fishery Management Plan* requires annual assessment of the southern rock lobster (*Jasus edwardsii*) stock in Victoria to enable a review of the stock and setting of the annual TACC (Victorian Fisheries Authority 2024).

The Victorian Rock Lobster Fishery is divided into two separately managed zones; the Western Zone and the Eastern Zone. The two zones are assessed separately and a TACC for each zone is determined using the fishery's harvest strategy. Each licence holder is then assigned a proportion of the zonal TACC based on the quota units attached to their licence. The quota units are transferable, through permanent sale or temporary lease, throughout the zone.

The data collected to assist in the assessment of the fishery against the reference points includes data from commercial catch and effort logbooks, a fixed-site survey program, an on-board observer program, puerulus sampling, in-port sampling of legal-sized rock lobsters (discontinued in 2016/17), and a voluntary sampling program (which has been expanded from 2016/17 onwards).

A new management plan and harvest strategy have been adopted and this assessment is the second to evaluate the fishery against the new reference points and harvest strategy.

The performance of the fishery is evaluated against the stock performance indicators and associated limit reference points specified in the fishery's harvest strategy. The key indicators are egg production, standardised CPUE and pre-recruit abundance. The annual TACC is determined using a set of decision rules:

Harvest Control Rule Part 1: Ensuring Egg Production LRP is met

Model estimated egg production must be above the limit reference point of 20 percent of the virgin level with a 90 percent probability. This decision rule must be satisfied before the CPUE-based harvest strategy can be used to set the TACC. In circumstances where a model-based estimate of egg production is unavailable a CPUE based proxy may be used to evaluate the fishery against a proxy

If this decision rule is not met, the TACC will be determined using the rock lobster fishery model to ensure that the TACC returns the egg production to above the limit reference point within two years with a 90 percent probability.

Harvest Control Rule Part 2: TACC Determination

When Decision Rule #1 has been met, the TACC is set using the standardised CPUE-TACC. Note that the HCR initially (at the time of its adoption) commences in Step 1.

1. The fishery will move to the next CPUE band (and possibly a higher TACC unless the cap has been reached) if:

i) the standardised CPUE is in a band higher than in the previous season;

AND

ii) the PRI (rounded to two decimal places) is at or above the threshold level of 1.67 undersize per pot lift for the Western Zone or 0.25 undersize per pot lift for the Eastern Zone.

Note that the CPUE band can only increase a single level per year. If the new CPUE band has reached the final value for that step (as indicated by the arrow) then the next step will be used for setting this TACC and the TACC in all subsequent years.

2. The TACC will remain at the same level and the same band when:

   i) the standardised CPUE remains in the current band;

OR

   ii) the standardised CPUE has increased to a higher band but the PRI is below the trigger point.

3. The TACC will be decreased when:

   i) the standardised CPUE has decreased into any lower band. In this circumstance the TACC will be set at the level that corresponds to the standardised CPUE band in the current step.

4. The harvest control rule will be reviewed when:

   i) The catch rate band decreases for two consecutive years; or
   ii) The PRI is below threshold for two consecutive years.

Both of the conditions in point 4 provide an early warning sign that the recruitment assumptions underpinning the harvest control rule may no longer be valid (as happened with the reduction in recruitment and productivity experience in the late 2000s). Consequently, a review of the harvest control rule to investigate this further will be required.

Available biomass is used as a secondary reference point. Whilst not used in the TACC determination it is monitored as part of the overall stock health. As the harvest strategy uses standardised CPUE, all references in this report (unless specified otherwise) are therefore standardised values.

The PRI is determined using data from fixed-site surveys and on-board observations and is averaged, weighting regions by their past commercial catch. The calculated PRI is then compared against the PRI threshold level, calculated as the 40th percentile of a normal distribution fitted to the PRI during a reference period of 2008 to 2022.

This report summarises the fishing activity and stock status of each zone for the 2023/24 season and provides the outputs from the southern rock lobster stock assessment model for the Western Zone, including estimated egg production and available biomass.

3. WESTERN ZONE ROCK LOBSTER FISHERY

3.1 FISHERY STATISTICS

Trends in catch, effort and CPUE

The TACC for the Western Zone in 2023/24 was 242 tonne (t), which was a decrease from the 246t TACC set between 2019/20 and 2022/23. In 2019/20, a 1t increase from the previous TACC was implemented due to a revision of the CPUE-TACC table in the harvest strategy (Table 3). This follows on from four years of 230t TACCs.

CPUE has remained constant in the Western Zone in 2023/24. Low PRI values have caused concern about future recruitment for several years, resulting in retention of a more precautionary TACC. For the 2023/24 season, a TACC reduction to 242t was implemented to align with the rebuilding plan under the new harvest strategy. This rebuilding plan was revised in early 2024 to include new information about recruitment, resulting in a TACC increase to 245t.

The effort required to take the catch was 190,213 pot-lifts, which is the lowest on record (Table 2, Figure 1). The reduction was largely attributable to increasing CPUE. Nominal CPUE has more than tripled since the lowest level in 2009/10, consequently effort to take the same amount of catch has reduced by over a third. The reduction in the number of pot-lifts required to catch the TACC drove the consolidation of the fleet from approximately 100 active vessels through the 1990s to 30 active vessels in 2023/24.

Trends in nominal and standardised catch rates have been consistent since the 1980's. A record low of 0.34 kg/pot-lift (standardised) was reached in 2009/10. Since then, standardised CPUE has been increasing and has reached 0.780 kg/pot-lift in 2022/23 and 0.785 kg/pot in 2023/24. This increased CPUE is now at levels not experienced since the 1980s (Table 2, Figure 2). Nominal and standardised CPUE have diverged in recent years – this is primarily due to a shift to a more efficient fleet (and fishing characteristics) that will have higher CPUE for the same biomass. The standardised CPUE removes this effect to provide the best index of stock abundance.

When examined by region, catch levels were relatively consistent with the previous year with a small shift from Apollo Bay and Portland to Warrnambool. The highest catch in 2023/24 came from the Portland region at 123t, followed by Apollo Bay at 60t and Warrnambool at 57t. Standardised catch rate increased in all regions, most significantly in Warrnambool (Figure 3).

Recreational Catch

On 1 July 2017, the VFA implemented a three-year pilot program requiring all recreational fishers to tag the lobsters they catch and keep; and report the use of tags. The objective of the program was to obtain an estimate of the annual recreational catch. The number of tags reported in that season was used to represent the number of rock lobsters removed from the stock.

On the back of the success of the trial, the Minister committed to an ongoing program. This has resulted in the annual collection of recreational catch data feeding into stock assessments, rather than relying on notional assumptions. At the start of the 2021 recreational rock lobster season, the rock lobster reporting program transitioned to an entirely digital platform, utilising a Victorian government smartphone app, GoFishVic.

Recreational catch estimates produced by this program are now intended for use in the stock assessment model. However, due to the disruptions from bushfires, COVID, and the data collection challenges transitioning to digital reporting, the most recent season of data considered reliable is the 2018/19 season. In the 2018/19 season 6,346 kg were reported as caught and retained by recreational fishers in the Western Zone. Weight was calculated by multiplying the average citizen science weight in the Western Zone, of 1.7kg, by the total number of tags reported that season, 3,734 tags. This is equivalent to 2.6% of the TACC in 2023/24 quota year, noting that the recreational fishing season runs between November and September.

Following the completion of the tagging trial, the average weight calculation was replaced by a length-weight relationship model. This model is derived from 165,000 lobsters measured and weighed in fish processors between 1995 and 2017. It is, therefore, considered to have a higher degree of accuracy. For context, by applying this model to the reported catch for 2018/19, the estimated total weight landed was 5,070 kg, equivalent to 2% of the TACC in the 2023/24 quota year.

In the 2023/24, 1,118 lobsters were reported by recreational fishers in the Western Zone, which is considered to be significantly less than the estimated total recreational harvest. Using the length-weight relationship, the estimated weight taken based on this data was 1,684 kg; equivalent to only 0.70% of the TACC that season. Despite a significant increases in reported catch from the 2022/23 season, this data is considered to be underreported.

Trends in the commercial fleet

The number of active fishing vessels decreased from a high of 140 in 1988/89 to approximately 100 through the 1990s, and to a record low 30 vessels in 2023/24 (Figure 5). During the same period the average annual catch increased from a record low of 2.4t per vessel in 1988/89 to 5.9t per vessel in 2000/01 and up to 7.9t in 2023/24 (Figure 6). The number of days fished also increased from a low in 1987/88 at 71 days per vessel to 156 days in 2000/01 and then declined to 63 in 2022/23 and remaining at 63 in 2023/24, this has occurred as the fleet contracted and the catch per vessel increased (Figure 6).

In the 2023/24 season, high CPUE and a reduction in fleet size to 30 (the lowest on record) led to an increase in the average annual catch to 7.9t and remained at 63 days of fishing in both 2022/23 and 2023/24. This is a record high in catch per vessel coupled with a low fishing effort per vessel. This trend in increased catch among a smaller number of vessels is consistent with fleet consolidation and efficiency gains expected from an individual transferrable quota (ITQ) system, however, in this fishery this has also largely been driven by changes in catch and TACC.

Note that the numbers reported in this section are for the fishing season and will differ from the licensing year summaries provide in Table 5. There was also a substantial revision in the time series of days fished per season in the previous 2022/23 assessment which had previously been reported incorrectly.

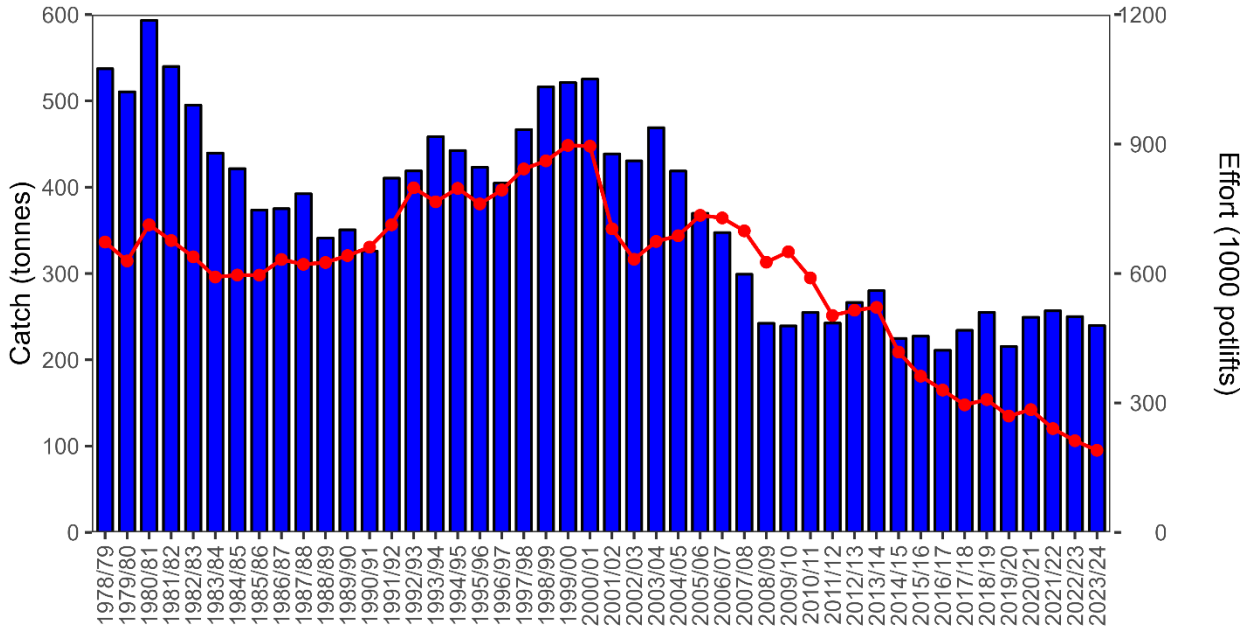

Figure 1: Total catch (blue bars; tonnes) and nominal effort (red line; x1000 pot-lifts) in the Western Zone.

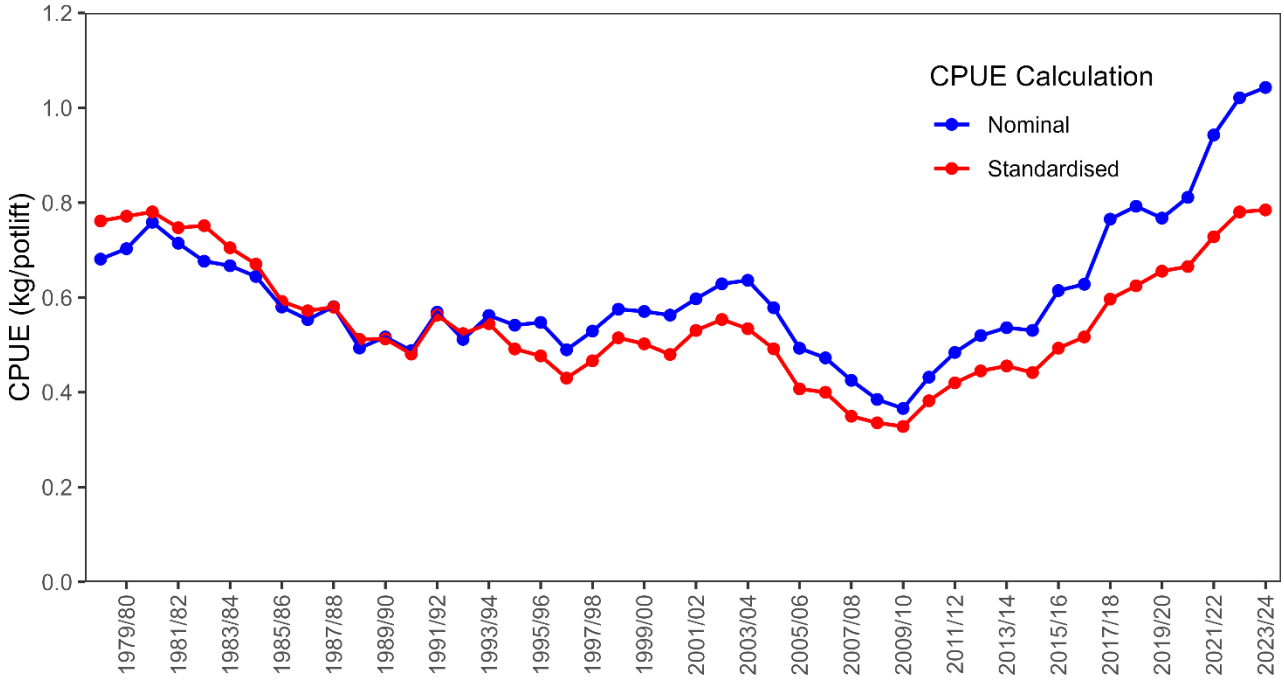

Figure 2: Standardised (red) versus nominal (blue) CPUE (kg/ pot-lift) in the Western Zone. Note that standardised CPUE values differ slightly from one assessment to the next as the depth, seasonal and fisher coefficients are shared across years and are re-estimated including the new data.

3.2 STOCK STRUCTURE DATA

Trends in recruitment

Catch rates of undersized lobsters (animals between approximately 80mm carapace length (CL) up to the legal minimum lengths (LML)) are estimated from the fixed-site surveys (closed escape gaps) and the on-board observer program (open escape gaps). The fixed-site surveys have been conducted each year since 2001/02 and the on-board observer program has been in place since 2004/05.

Undersize catch rates differ between areas and between the fixed site surveys and the on-board observer program. Consequently, calculating a pre-recruitment index (PRI) by simply averaging across the entire dataset would result in changes in observer coverage influencing the PRI value in a way that is unrelated to real changes in undersize abundance. To address this both the observer and fixed site PRIs are calculated for a number of pre-determined areas which are then combined ensuring that the contribution of each area remains consistent through time. The observer-based PRI is also scaled so that its mean value matches that of the fixed site PRI, this enables these two data sources to be combined in a way that gives them equal importance.

The PRI indices calculated from both data sources show similar trends with a rapid decline from the recent peak in 2011/12 to a record low in 2015/16. Since that time PRI has been trending upwards with values in the last three years above the threshold level of 1.67 undersize per pot-lift (Figure 7). The most recent 2023/24 value is 1.82 undersize per pot-lift which is a decline from 1.97 in 2022/23. Observer and fixed site PRI have been highly correlated indicating consistent signals in both data sources and providing confidence in the representativeness of these indices.

As a consequence of COVID restrictions, full coverage was not obtained in the observer program in 2019/20. The observer sites that were completed are by chance those with typically the lowest PRI (Port Fairy and Warrnambool), consequently the PRI was considered incomplete for the 2019/20 assessment period.

Mean weight

The mean weight of legal sized lobsters increased between 2011/12 and 2019/20 to a record high of 1.04kg (Figure 8). After two years of decreases it has again reached a record high in 2022/23 (1.05kg) and again in 2023/24 with 1.06 kg per lobster The overall increase in average lobster weight observed since 2011/12 is an additional indicator of the recruitment reduction that has taken place, with the current high catch rates obtained through a reduced exploitation rate applied to a broader range of size classes. However, it has been noted there has also been a disproportionate increase in the beach price of large lobsters. Anecdotal reports suggest this has influenced fishing behaviour and selectivity, thereby contributing to an increase in mean lobster weight.

Length-frequency distributions

In addition to numbers of undersize lobsters, the fixed-site surveys and observer program collect data on the length-frequency distribution of lobsters in the population. The trends in the length-frequency data are consistent with the trends in pre-recruits and legal-size commercial catch rates. From the late 2000s to 2019/20 there was a substantial decrease in the abundance of small lobsters including both animals below the LML and animals within approximately 10mm of the LML. The CPUE has been maintained at a high level through an increase in abundance of larger animals. This dramatic change is highlighted in Figure 9 with full length-frequency details provided in Figure 29 to Figure 32. The exception to this general trend occurred in the last two seasons which have showed an increase across animals below the LML in both observer and fixed sites.

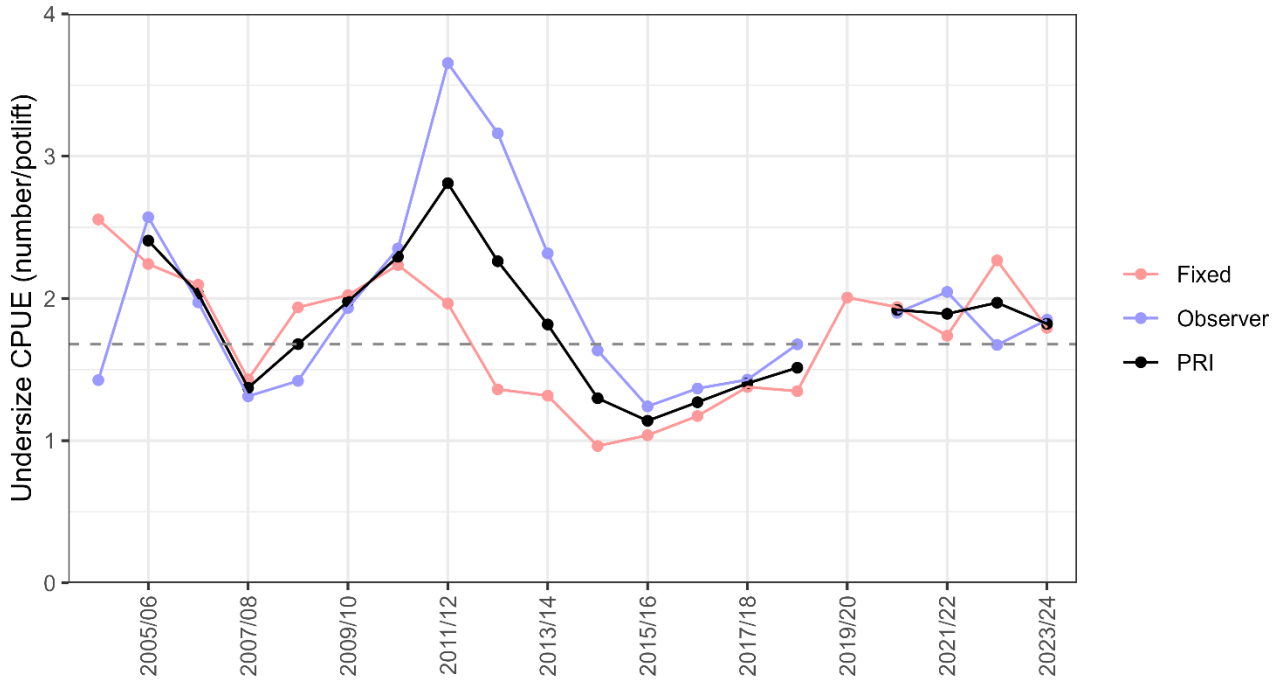

Figure 7: The undersize catch rate (kg/pot-lift) for the Western Zone as calculated from fixed sites (red), observer coverage (blue) and the final combined PRI (black). The dashed line shows the trigger point (1.67 undersize/pot-lift). A PRI value for 2019/20 was unavailable due to limited coverage resulting from COVID restrictions.

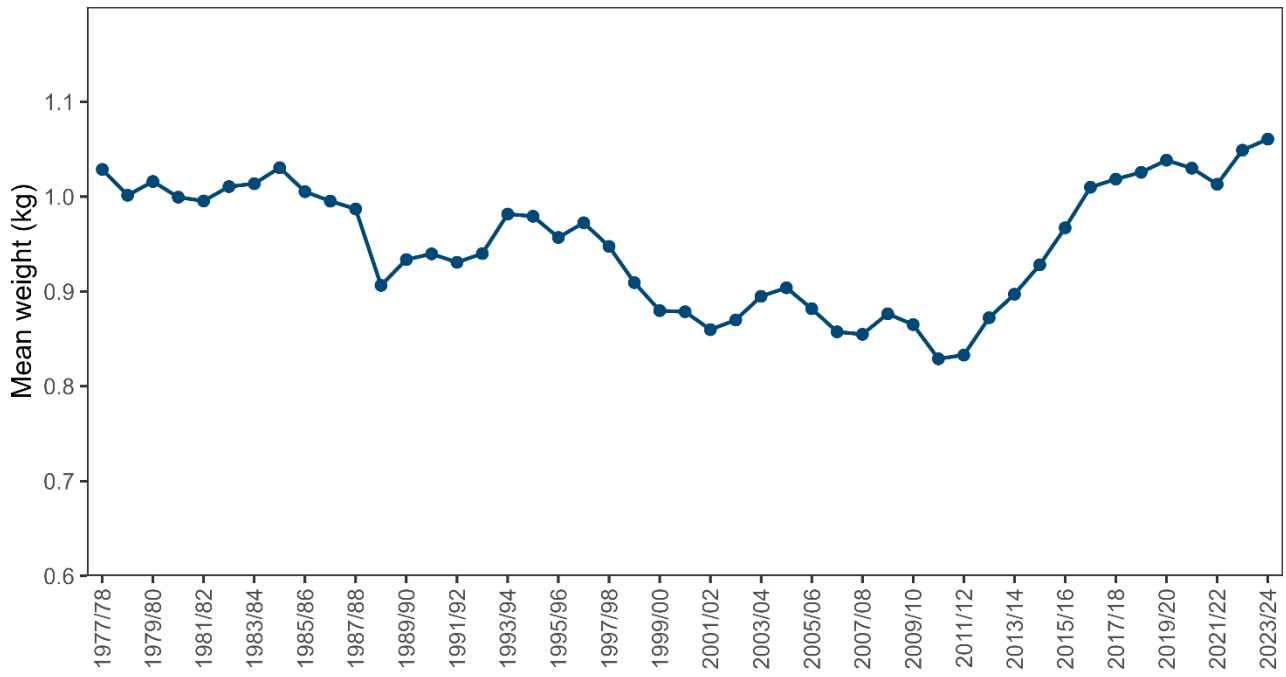

Figure 8: Mean weight of legal-sized lobster in the Western Zone fishery.

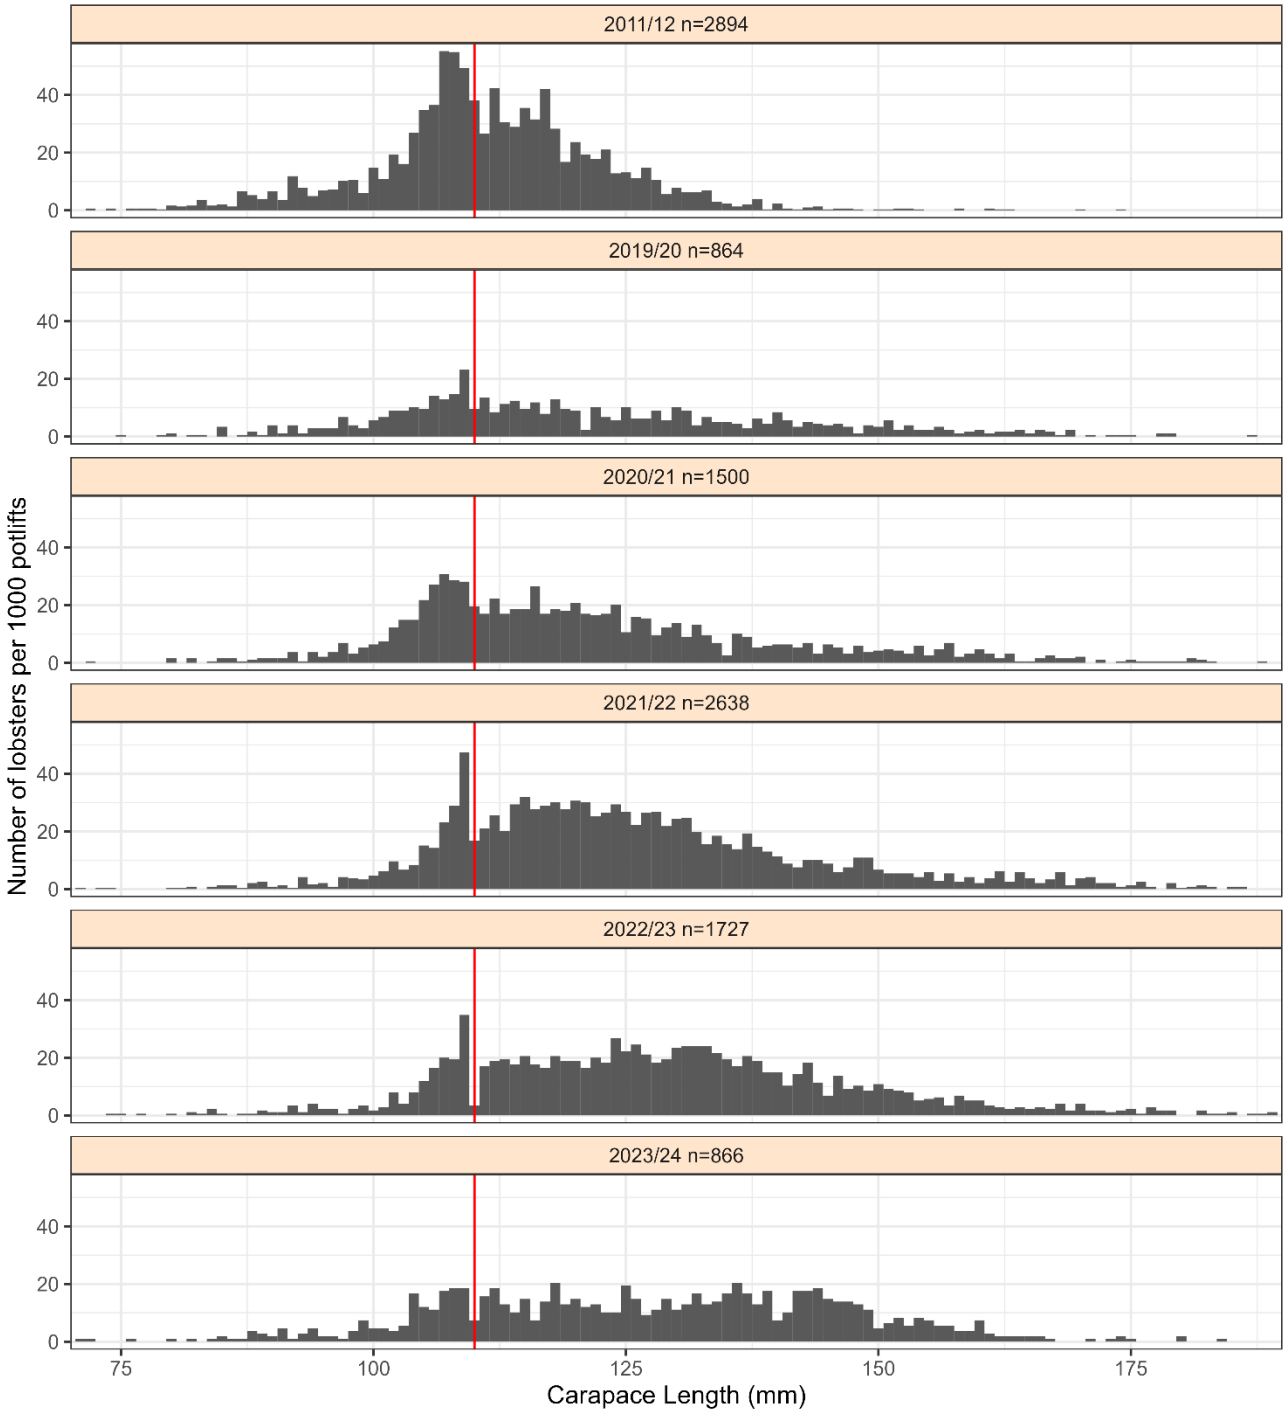

Figure 9: Length-frequency plots for 2011/12 and the last five seasons for male lobsters measured by the Western Zone observer program to highlight the changes that have occurred. The red line indicates the legal size limit.

3.3 MODEL OUTPUTS

Estimated recruitment

Recruitment is reported as the number of new lobsters passing the 60mm CL size in a given year. It is difficult to obtain information about lobsters of this size directly as they are much less likely to be retained in pots (as recorded on observer and fixed site sampling trips) and do not influence the commercial CPUE. Consequently, reliable estimation of the recruitment in a given year requires observation of that age class over several years. As the lobsters grow, they are observed through multiple fixed site surveys and observer trips and ultimately influence commercial CPUE. These multiple observations are combined with information about lobster growth through the stock assessment model to give the best estimate of recruitment in each year. Due to this the most recent recruitment estimates (e.g. for 2023/24) are highly uncertain and are not shown, whilst the most recent estimates shown (e.g. 2019/20) are more likely to change in future years as more information becomes available about these year classes.

Model estimated recruitment to 60mm CL has been highly variable over the past 30 years, with a distinct change in the relative abundance over the length of the time series. Between 1988/89 and 1999/00, recruitment was mostly above the long-term average. Conversely, from 2001/02 onwards, with the exception of 2007/08 and 2008/09, recruitment has been well below the average (Figure 10). It is for this reason that stock recovery under the lower catch levels implemented in the last 15 years has been slow.

Estimated egg production

It should be noted that whilst trends in egg production are consistent across stock assessments, the absolute values may all scale up or down as different parameter estimates are obtained.

The harvest strategy sets a model estimated egg production limit reference point of 20% of unfished levels. The Western Zone egg production has never fallen below the limit reference point. In 2022/23 egg production was at 23.0% but declined to 22.0% in 2023/24 which is above the 20% limit reference point (Figure 11). There has been a gradual decline in egg production over the last three years from a high of 24.0% in 2020/21 (revised from previous assessment). However some of this decline is due to the negative bias in the most recent egg production estimate (see model diagnostics and biases section).

In addition to the existing approach for calculating egg production, a new method has been applied in parallel in the last two assessments. This method gives a more consistent probabilistic evaluation of egg production. The key benefits are that i) the estimate of the unfished pre-exploitation level of egg production is updated in each stock assessment on the basis of new information and ii) the current level of egg production is evaluated against this in a probabilistic manner that takes into account recruitment variability. A probability distribution derived from this method is shown in Figure 12. This provides additional evidence that egg production exceeds the 20% limit reference point with a >90% probability as required by the harvest strategy. Note that the two methods produce somewhat different results in magnitude but are broadly consistent and both meet the requirements of the harvest strategy.

Estimated available biomass and exploitation rate

It should be noted that whilst trends in biomass and exploitation rate are consistent across stock assessments, the absolute values may all scale up or down as different parameter estimates are obtained.

Under the increasing exploitation rates experienced between 1980/81 and 2000/01, the modelled available biomass indicates a downward trend for the first decade before entering a phase of stability fluctuating around 850t between 1987/88 to 2003/04. Exploitation rates dropped in 2001/02 with the introduction of quota, but steadily increased to a historical high of 67% in 2006/07. The corresponding available biomass decreased and reached a low of 447t in 2008/09. After 2006/07, the exploitation rate dropped significantly,

and the available biomass improved. In 2023/24, the estimated available biomass decreased to 851t, with a corresponding fishing exploitation rate of 28.2% (Figure 13).

Model diagnostics and potential biases

Two key datasets that the stock assessment model is fitted to are the standardised CPUE data and length-frequency data. In the Western Zone data set there has long been a level of inconsistency between undersize lobster estimates from length-frequency data and stock productivity in subsequent years. The CPUE in future years tends to be higher than expected given the catch and the level of undersize observed at present. Consequently, model biomass and egg production estimates for the most recent year tend to be underestimates and tend to be revised upwards in subsequent years as new data becomes available. This known issue leads to a precautionary perspective and is being investigated in more detail as part of the trial of the new Australian Lobster model.

Selected model diagnostics for both data sets are shown in Figure 33 and Figure 34. These show that the model generally fits well to both datasets (note that CPUE fits in the lower catch periods (e.g. period 10) are of less importance). However, as shown in Figure 14, CPUE in the most recent year is slightly under-estimated and consequently the 2023/24 biomass and egg production estimates are likely to be similarly slightly under-estimated.

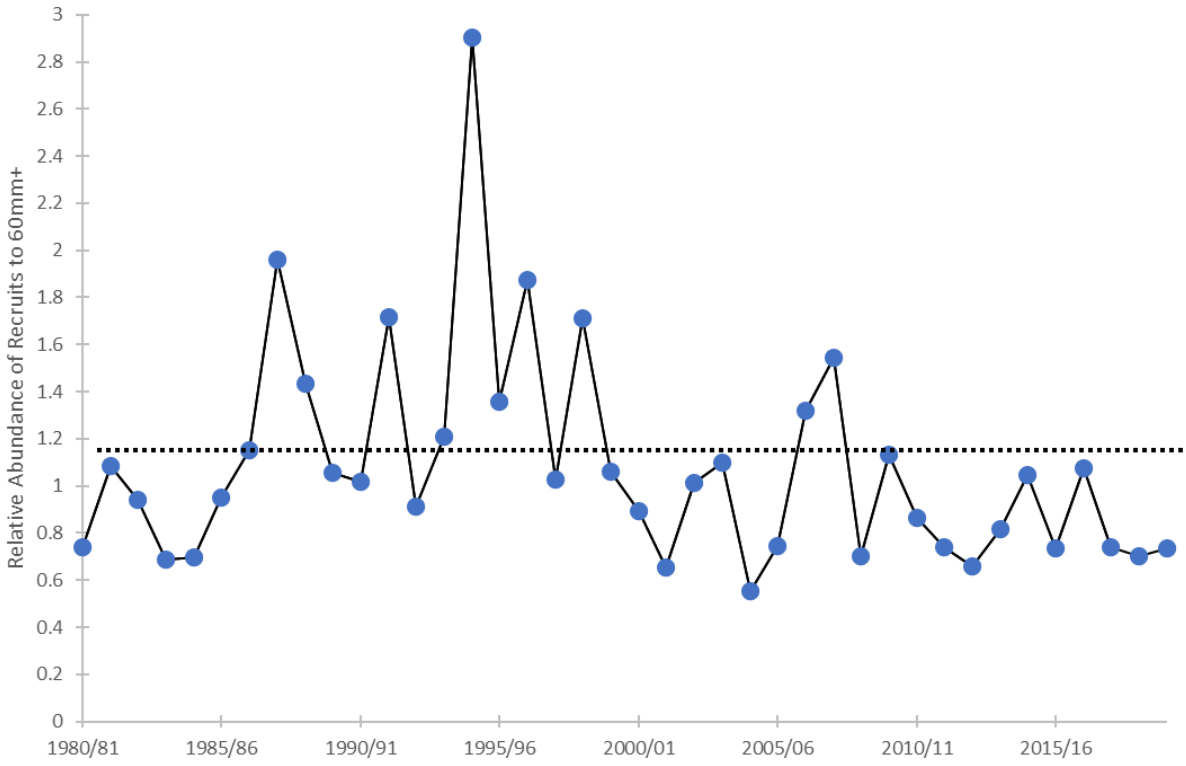

Figure 10: Relative number of recruits (to 60 mm in CL) in the Western Zone Fishery. These results are generated by the stock assessment model. The long-term average is indicated by the dotted black line. The most recent values are based on fewer observations and are therefore more likely to change in future stock assessments as more information about that year class becomes available.

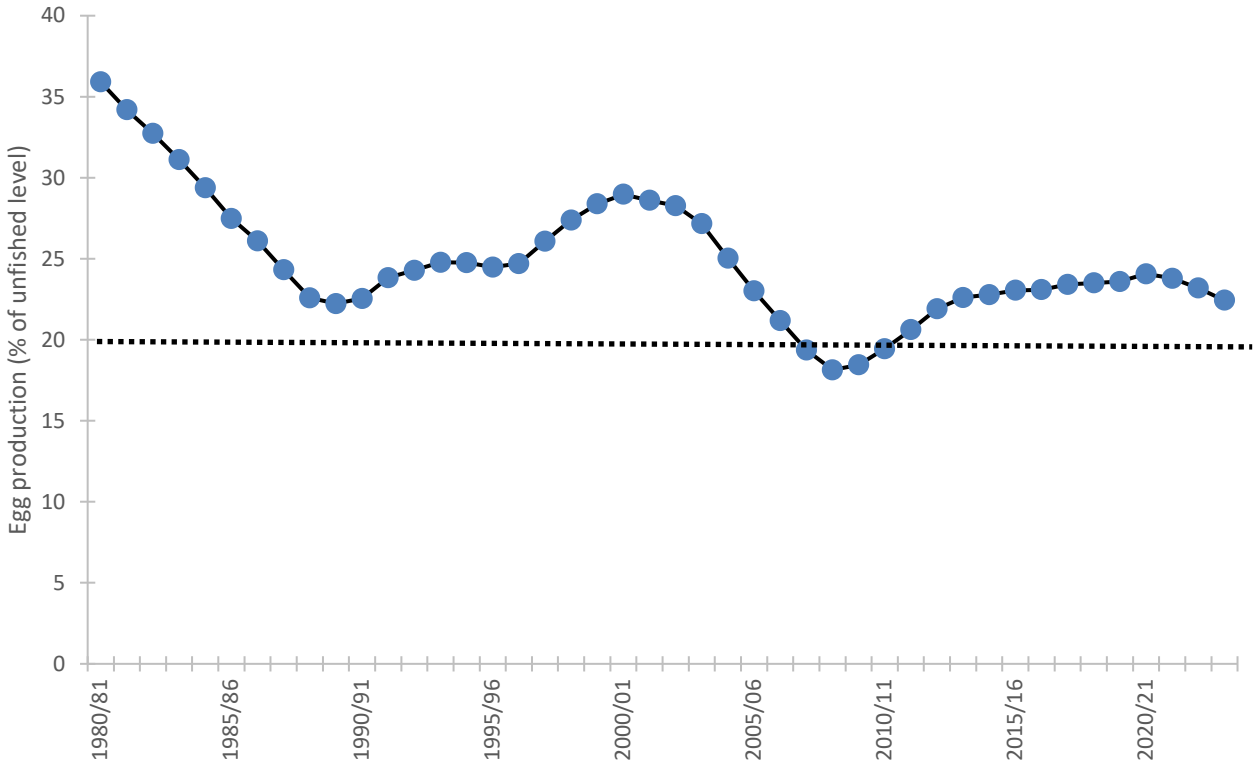

Figure 11: Model estimated level of egg production through time in the Western Zone fishery. The limit reference point (dotted line) is 20% of unfished levels.

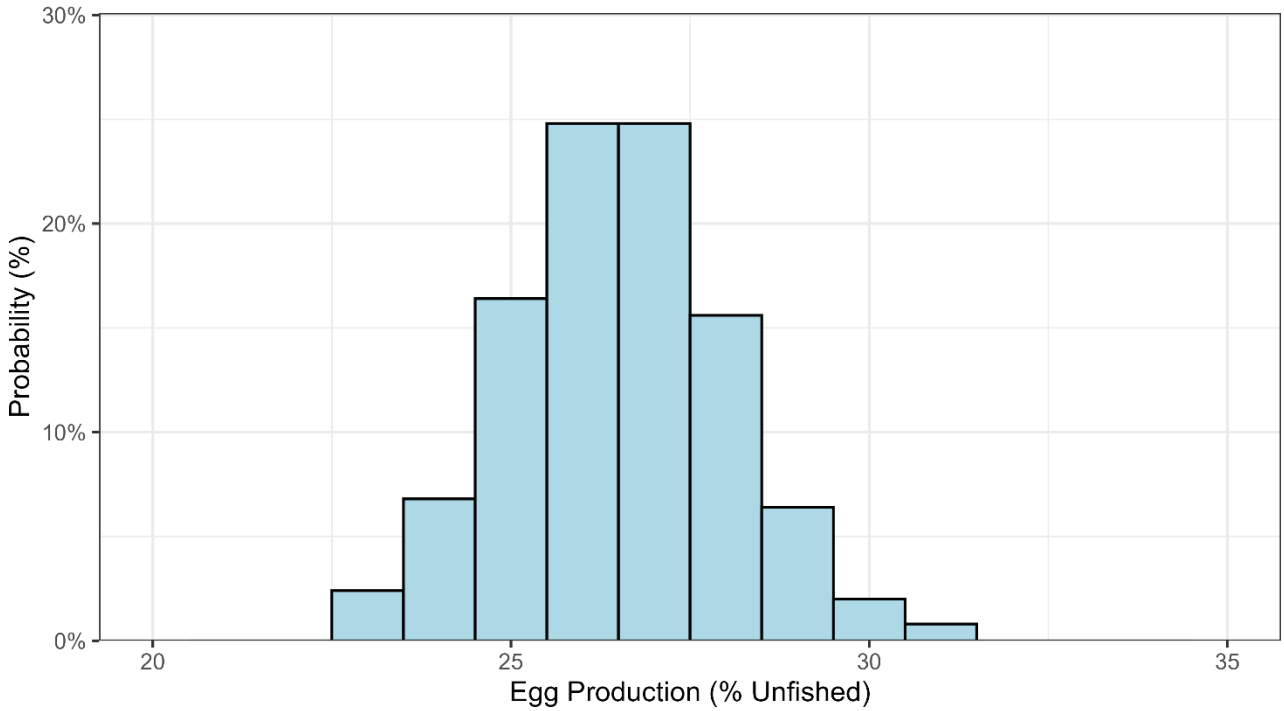

Figure 12: Probability distribution of model estimated egg production in 2022 compared to the unfished level of egg production in the Western Zone.

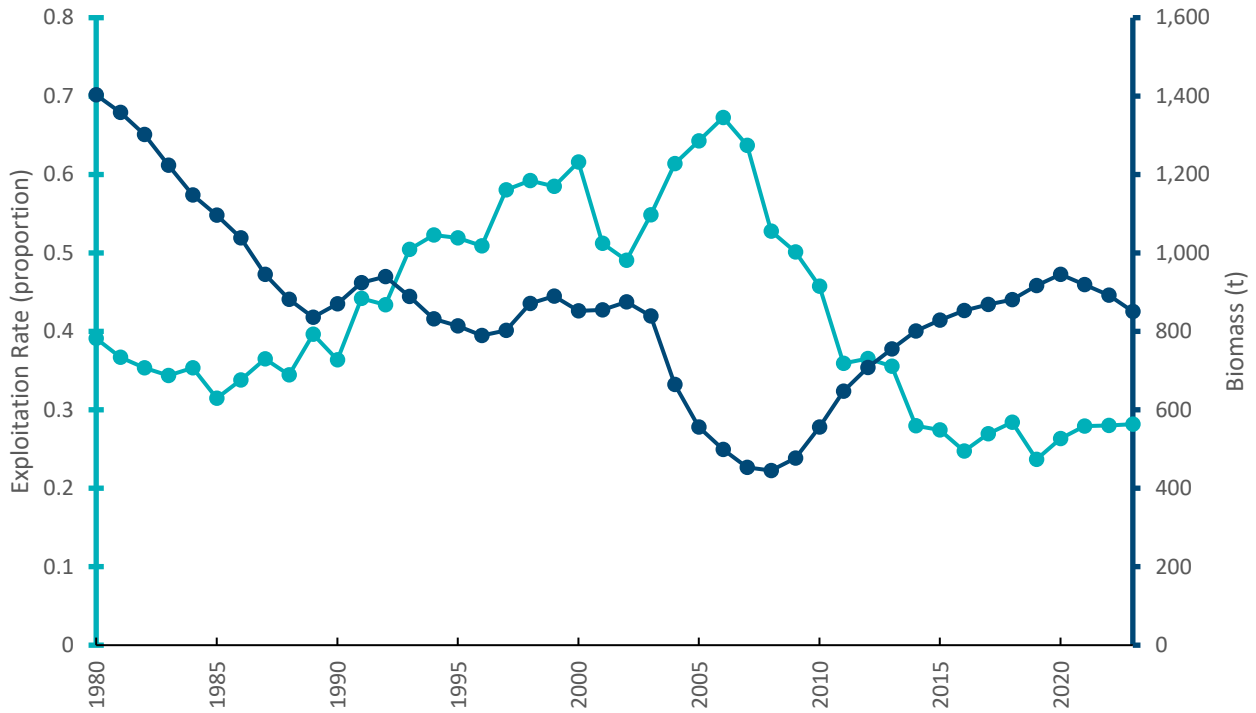

Figure 13: Model estimated levels of available biomass (dark blue) and associated fishing exploitation rates (light blue) in the Western Zone fishery.

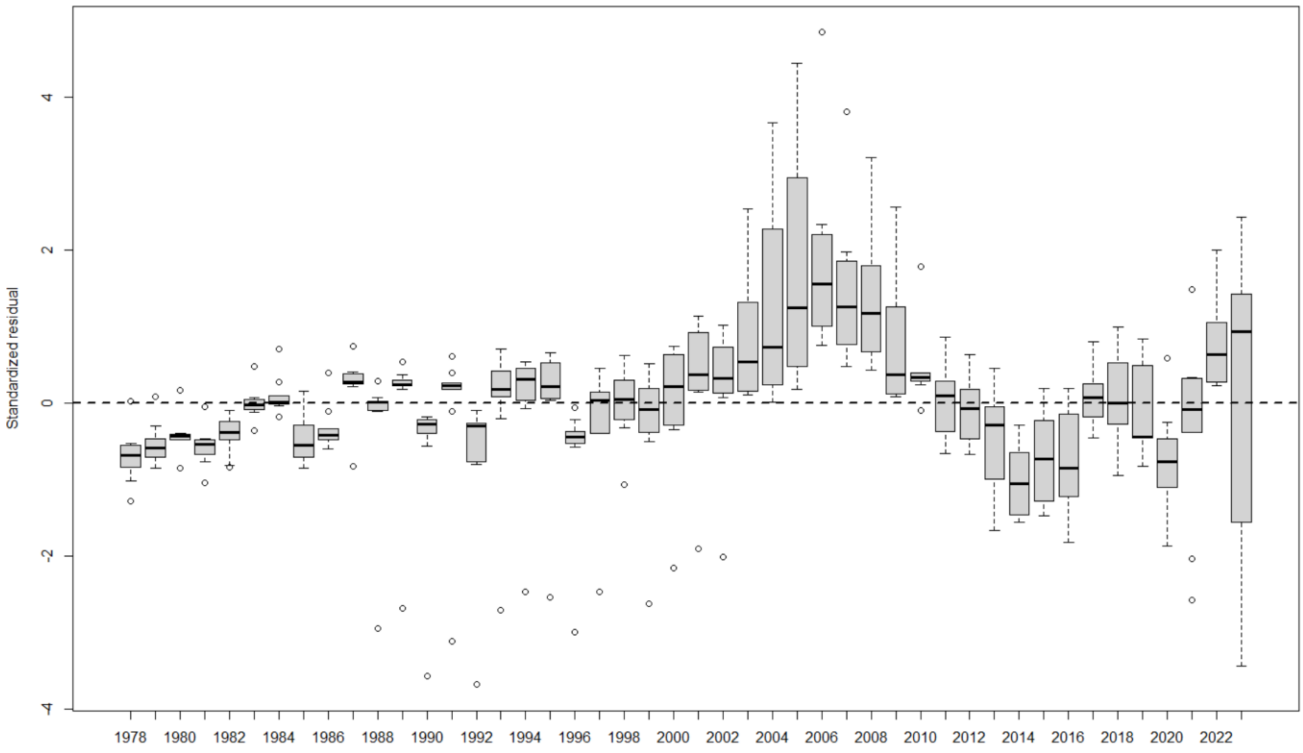

Figure 14: Standardised residuals for CPUE in the Western Zone. Where values are positive they indicate that the model is under-estimating CPUE and negative values indicate that the model is over-estimating CPUE.

3.4 APPLICATION OF THE HARVEST STRATEGY

The annual TACC is set on the basis of the response to the decision rules contained within the harvest strategy as described below.

Decision Rule	2023/24 Stock Indicator Level	Outcome
Part 1: Egg Production		
Is the model estimated egg production above the limit reference point of 20% of unfished levels?	The 2023/24 egg production level is estimated at 22.4% of unfished levels.	Decision rule has been met. Go to Part 2
Part 2: TACC Determination		
a. Is standardised CPUE in a higher band than the previous season?	CPUE decreased from 0.79kg/pot-lift in 2022/23 to 0.78kg/pot-lift in 2023/24. This remains in the same 0.75-0.80 CPUE band	The CPUE band has remained the same.
a. Is the 2022/23 PRI at or above the threshold level of 1.67 undersize/pot-lift?	The combined PRI was 1.82 in 2023/24. This was a slight reduction from the previous three years but remains above the threshold level.	The combined PRI is above the threshold level.
	RESULT	**The Western Zone remains in the CPUE band 0.75-<0.80. This gives a TACC of 245t in 2025/26.**

Establishing the WZ TACC for 2025/26

A direct application of the decision rules in the harvest strategy specifies that the TACC remains in the same 0.75-0.80 CPUE band in Step 2.

In summary:

- **The CPUE band is 0.75-<0.80.**
- **Remain at step 2.**
- **A TACC of 245t should be set.**

4. EASTERN ZONE ROCK LOBSTER FISHERY

4.1 FISHERY STATISTICS

Trends in catch, effort and CPUE

The TACC in 2023/24 was 21t (Table 5). In 2021/22 and 2022/23, the Eastern Zone TACC was 32t, which was a reduction from 40t in 2020/21 and 47t in 2018/19 following a previous extended period of TACCs in the 59-66t range. The TACC reductions since 2018/19 have been due to ongoing declines in CPUE resulting from reduced recruitment. In 2021/22 and 2022/23, there has been a significant under-catch driven by a combination of low CPUE and economic circumstances. The proportion of TACC caught was higher in 2023/24 which was driven by both an increase in catch and decrease in TACC.

Standardised CPUE reached a twenty-year peak of 0.63kg/pot-lift in 2012/13 but fell rapidly to a record low of 0.36 in 2017/18. From this record low the CPUE has gradually risen to 0.48 in 2022/23 and increased to 0.60 in 2023/24 (Figure 16, Table 4). Note that standardised CPUE values differ slightly from one assessment to the next as the depth, seasonal and fisher coefficients are shared across years and are re-estimated including the new data. Consequently the 2022/23 standardised CPUE estimate decreased from 0.49 to 0.48kg/pot-lift.

In addition to the substantial TACC decreases there has been a significant under-catch of the TACC with 63% caught in 2021/22 and 46% caught in 2022/23. However, this increased to 87% in 2023/24. In 2022/23 standardised CPUE increased in Queenscliff, San Remo and Lakes Entrance (Figure 17). However, due to the lack of data the San Remo CPUE value provides limited information and the decline observed in Lakes Entrance is meaningless. This presents an ongoing issue for the new management plan which (like its predecessor) is reliant on a zone wide standardised CPUE.

Recreational Catch

On 1 July 2017, the VFA implemented a three-year pilot program requiring all recreational fishers to tag the lobsters they catch and keep; and report the use of tags. The objective of the program was to obtain an estimate of the annual recreational catch. The number of tags reported in that season was used to represent the number of rock lobsters removed from the stock.

On the back of the success of the trial, the Minister committed to an ongoing program. This has resulted in the annual collection of recreational catch data feeding into stock assessments, rather than relying on notional assumptions. At the start of the 2021 recreational rock lobster season, the rock lobster reporting program transitioned to an entirely digital platform, utilising a Victorian government smartphone app, GoFishVic.

Recreational catch estimates produced by this program are now intended for use in the stock assessment model. However, due to the disruptions from bushfires, COVID, and the data collection challenges transitioning to digital reporting, the most recent season of data considered reliable is the 2018/19 season. In the 2018/19 season 6,202 kg were reported as caught and retained by recreational fishers in the Eastern Zone. Weight was calculated by multiplying the average citizen science weight in the Eastern Zone, of 2.0kg, by the total number of tags reported that season, 3,101 tags. This is equivalent to 29.5% of the TACC in 2023/24 quota year, noting that the recreational fishing season runs between November and September.

Following the completion of the tagging trial, the average weight calculation was replaced by a length-weight relationship model. This model is derived from 165,000 lobsters measured and weighed in fish processors between 1995 and 2017. It is, therefore, considered to have a higher degree of accuracy. By applying this model to the reported catch for 2018/19, the estimated total weight landed was 5,025 kg, equivalent to 23.9% of the TACC in the 2023/24 quota year.

In the 2023/24 season, 833 lobsters were reported by recreational fishers in the Eastern Zone, which is considered to be significantly less than the estimated total recreational harvest. Using the length-weight

relationship, the estimated weight taken based on this data was 1,336 kg; equivalent to 6.4% of the TACC that season. Despite significant increases in catch reported from the 2022/23 season, this data is considered to be significantly underreported.

Trends in the commercial fleet

The number of active fishing vessels decreased from 90 in 1978/79 to approximately 50 through the 1990s and further declined to the current record low of 11 active vessels in 2023/24 (Figure 19). The average annual catch increased from a record low of 1t per vessel in 1988/89 to a record high of 2.7t per vessel in 2014/15 (Figure 20). The number of days fished was also at a record low in 1988/89 at 63 days per vessel (Figure 20). This subsequently increased as the fleet contracted and the catch per vessel increased. In 2022/23 the average annual catch had reduced to 1.3t / vessel whilst the average number of days fished per vessel has decreased from a record high of 122 days in 2009/10 to 76 days in 2022/23. However, in 2023/24 average annual catch increased to 1.6t, the highest catch since 2019/20, while the number of days fished also increased to 84, the highest number of fishing days since 2018/19.

It should be noted that these statistics include only the Eastern Zone catch, but include vessels that fish both zones, thereby the catch per vessel is lower than may be expected. Also note that the numbers reported in this section are for the fishing season and will differ from the licensing year summaries provide in Table 5. There was also a substantial revision in the time series of days fished per season in the previous 2022/23 assessment which had previously been reported incorrectly.

4.2 STOCK STRUCTURE DATA

Trends in recruitment

Undersize catch rates differ between areas and between the fixed site surveys and the on-board observer program. Consequently, calculating a pre-recruitment index (PRI) by simply averaging across the entire dataset would result in changes in observer coverage influencing the PRI value in a way that is unrelated to real changes in undersize abundance. To address this both the observer and fixed site PRIs are calculated for a number of pre-determined areas which are then combined ensuring that the contribution of each area remains consistent through time. The observer-based PRI is also scaled so that its mean value matches that of the fixed site PRI, this enables these two data sources to be combined in a way that gives them equal importance.

The PRI indices calculated from both fixed-site surveys and on-board observers show similar trends with a rapid decline from the recent peak in 2013/14 to a record low of 0.08 undersize/pot-lift in 2018/19. Over the following three seasons PRI has increased considerably, reaching 0.32 undersize per pot-lift in 2021/22. This is the highest value in eight years and above the threshold level, however in 2022/23 PRI fell back to a near record low level of 0.09. In 2023/24, a new record low was set of 0.02 undersize/pot-lift (Figure 21).

Mean weight

The mean weight of Eastern Zone lobsters has always been higher than those from the Western Zone due to faster growth rates in the eastern area. However, since 2012/13 (when CPUE peaked), the mean lobster weight has increased from 1.12 kg/lobster to the highest mean lobster weight on record for the Eastern Zone of 1.51kg/lobster in 2019/20 (Figure 22). This high mean lobster weight in combination with the CPUE decline during this period is indicative of a lack of a recent recruitment to the legal biomass combined with a pulse of larger lobsters that are growing through the size classes. The mean lobster weight increased to 1.42 kg in 2023/24 from 1.31kg in 2022/23.

It should also be noted that there has been a disproportionate increase in the beach price of large lobsters. Anecdotal reports suggest this has influenced fishing behaviour and selectivity, thereby contributing to an increase in mean lobster weight.

Length-frequency distributions

Despite the small sample sizes in the Eastern Zone fixed-site surveys and observer program, the trends in the undersize lobsters support those observed in other data sets. Both programs have shown a dramatic decrease in catch rates of lobsters less than approximately 150mm through to 2018/19. This change is highlighted in Figure 23 and full details are given in Figure 35 to Figure 38. In the subsequent three years there has been an increase in abundance of smaller lobsters, this is most evident in the fixed site survey data. However, in 2022/23 and 2023/24 there was an alarming reduction in the abundance of small lobsters leading to the lowest PRI on record in 2023/24.

Egg Production

The normal full stock assessment process was not conducted for the Eastern Zone for 2022/23. Hence the Eastern Zone could not be assessed against the Egg Production Limit reference point in the usual manner. Instead, a weight of evidence approach is used here. The 2021/22 assessment indicated that egg production was well above the limit reference point with a high level of confidence (see following section and figures from the 2021/22 assessment model). The substantial increase in standardised CPUE since the 2021/22 assessment model indicates that egg production from legal size lobsters is likely to have increased. In contrast the PRI has reduced to record low levels indicating egg production from sub-legal mature females is

likely to have decreased. The combined effect on egg production of these two elements is unclear and there is greater uncertainty with less data available, however there have been previous years with low PRI and lower CPUE (e.g. 2018/19) in which egg production readily exceeded the limit reference point. In addition, the harvest strategy sets a CPUE proxy for a 20% egg production level of 0.25kg/pot-lift. This is readily exceeded with the current level of 0.60kg/pot-lift. Consequently, it is highly likely that egg production remains above the limit reference point in the Eastern Zone.

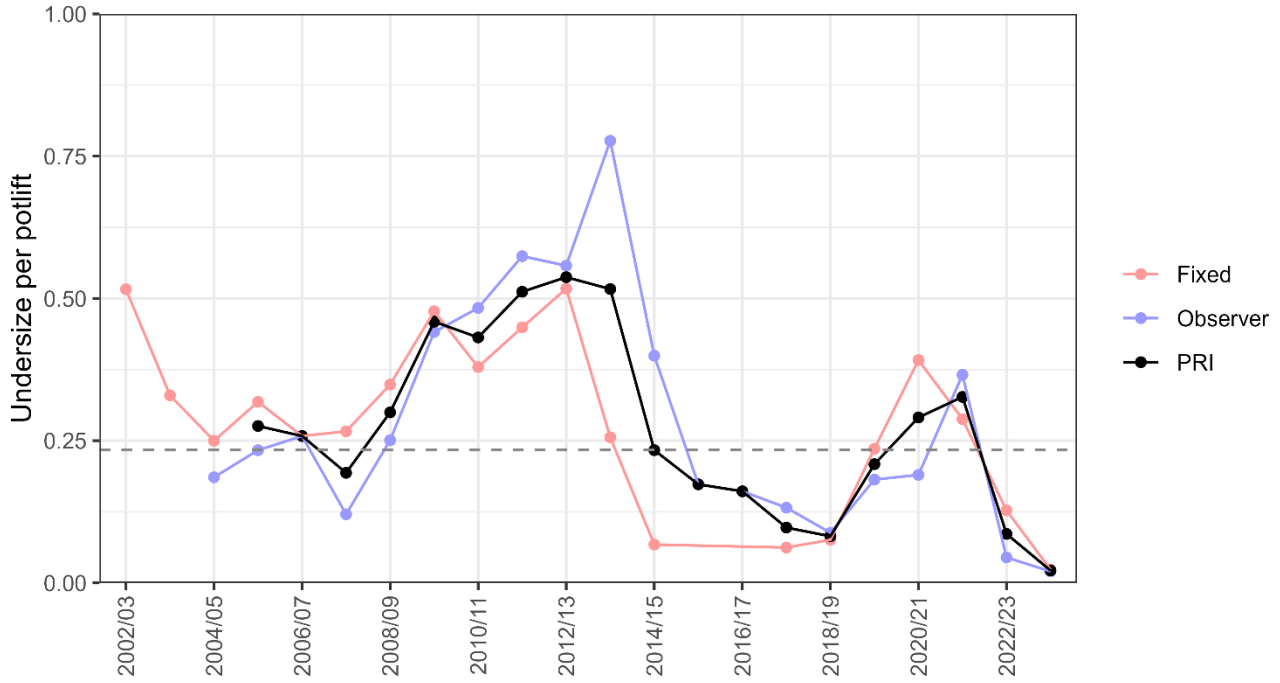

Figure 21: The undersize catch rate (kg/pot-lift) for the Eastern Zone as calculated from fixed sites (red), observer coverage (blue) and the final combined PRI (black). The dashed line shows the trigger point (0.25 undersize/pot-lift).

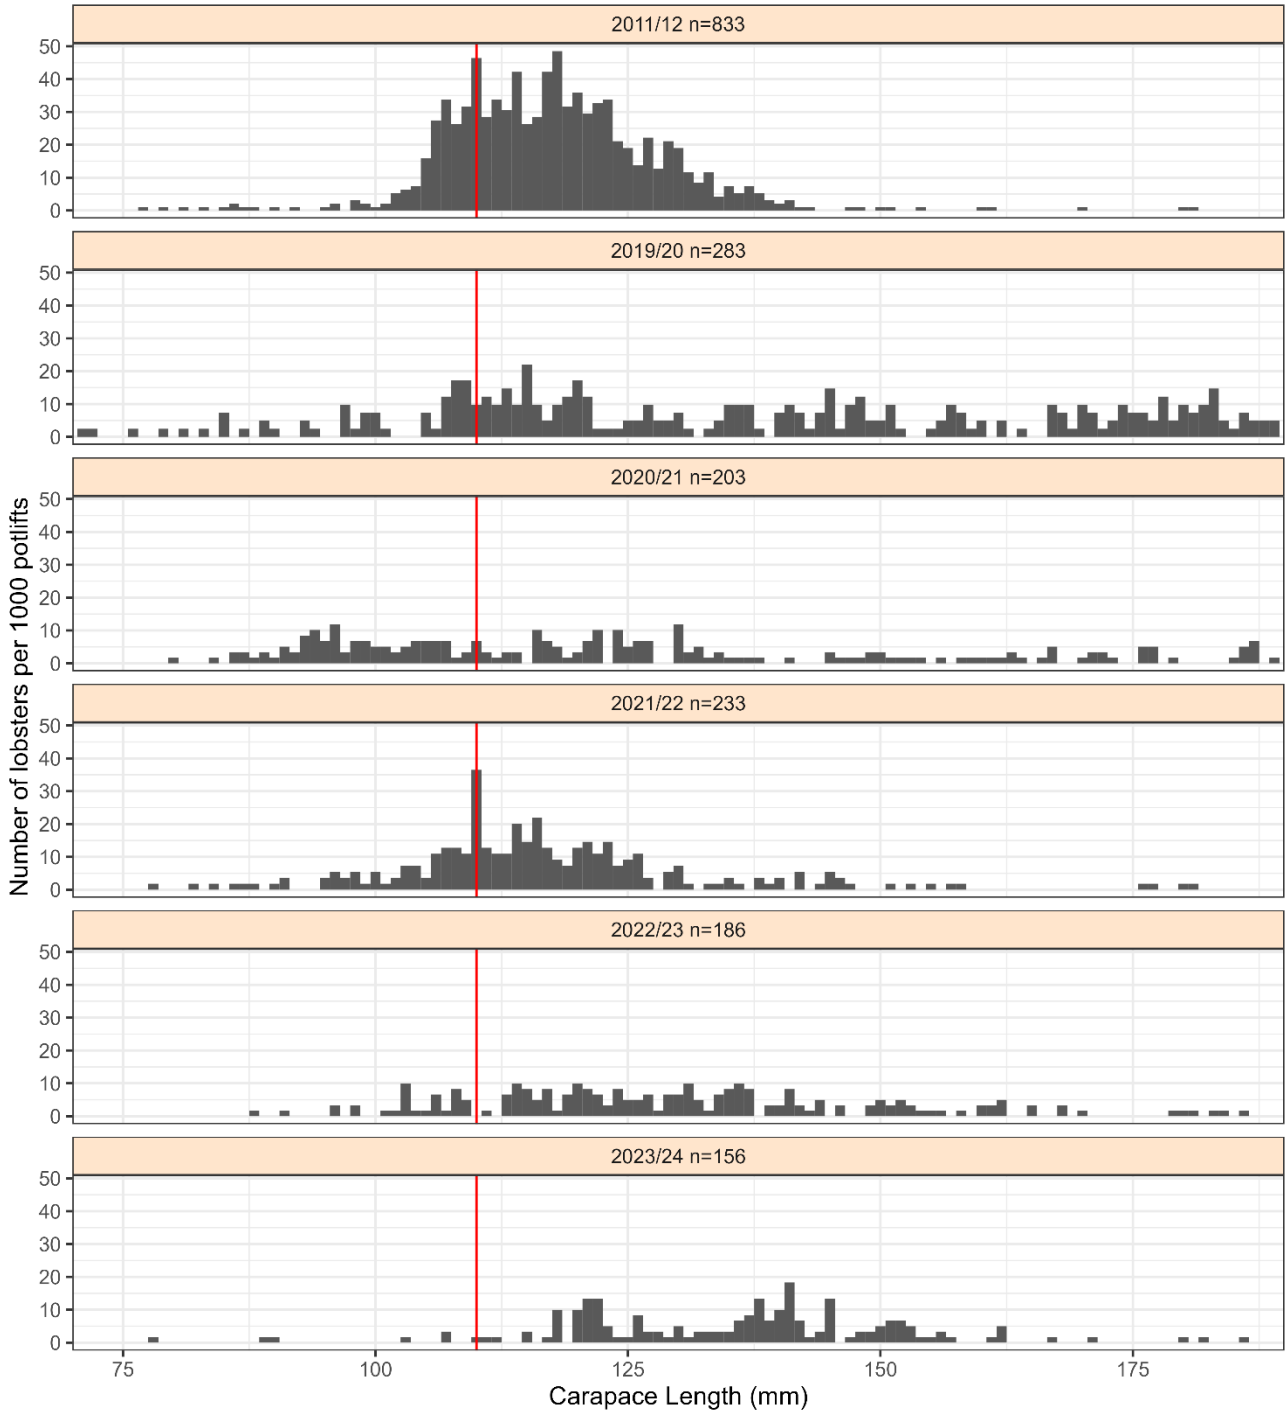

Figure 23: Length-frequency plots for 2011/12 and the last five seasons for male lobsters measured by the Eastern Zone fixed site program to highlight the changes that have occurred. The red line indicates the legal size limit.

4.3 MODEL OUTPUTS (FROM 2021/22 ASSESSMENT MODEL)

NOTE: The assessment model was not run for the Eastern Zone for the 2023/24 season. The most recent stock assessment model results from the 2021/22 season are included here for reference.

Estimated recruitment (from 2021/22 assessment model)

Recruitment is reported as the number of new lobsters passing the 60mm CL size in a given year. It is difficult to obtain information about lobsters of this size directly as they are much less likely to be retained in pots (as recorded on observer and fixed site sampling trips) and do not influence the commercial CPUE. Consequently, reliable estimation of the recruitment in a given year requires observation of that age class over several years. As the lobsters grow, they are observed through multiple fixed site surveys and observer trips and ultimately influence commercial CPUE. These multiple observations are combined with information about lobster growth through the stock assessment model to give the best estimate of recruitment in each year. Due to this the most recent recruitment estimates (e.g. for 2021/22) are highly uncertain and are not shown, whilst the most recent estimates shown (e.g. 2017/18) are more likely to change in future years as more information becomes available about these year classes.

The long-term time series for the model estimated recruitment to the 60mm CL size class shows that recent recruitment has been below the long-term average more than it has been above it. Levels have been low since 2009/10 and reached a historical low of 27% of the long-term average in 2013/14. Values have been higher in the last three years for which estimates are available but remain well below the long-term average (Figure 24). The higher recruitment estimates are in line with the recent increase in PRI from record low levels.

Estimated egg production (from 2021/22 assessment model)

It should be noted that whilst trends in egg production are consistent across stock assessments, the absolute values may all scale up or down as different parameter estimates are obtained.

Eastern Zone egg production levels reached a historical low in 1995/96 of 20.4% of unfished levels. After this time there was a steady increase to a recent high of 33% in 2013/14. Since 2013/14 there has been an ongoing decline to 22.9% in 2021/22, but this remains above the 20% limit reference point (Figure 25).

In addition to the existing approach for calculating egg production, a new method was applied in parallel in this assessment. This method gives a more consistent probabilistic evaluation of egg production. The key benefits are that i) the estimate of the unfished pre-exploitation level of egg production is updated in each stock assessment on the basis of new information and ii) the current level of egg production is evaluated against this in a probabilistic manner that takes into account recruitment variability. A probability distribution derived from this method is shown in Figure 26. This provides additional evidence that egg production exceeds the 20% limit reference point with a >90% probability as required by the harvest strategy. Note that the two methods produce somewhat different results in magnitude but are broadly consistent and both meet the requirements of the harvest strategy.

Estimated available biomass and exploitation rate (from 2021/22 assessment model)

It should be noted that whilst trends in biomass and exploitation rate are consistent across stock assessments, the absolute values may all scale up or down as different parameter estimates are obtained.

After a long period of stability at around 210t, biomass increased between 2009/10 and 2013/14 to a peak of 295t. As a result of low recruitment, biomass then decreased to 172t in 2019/20. In 2021/22 an increase to 186t was estimated. As a result of the low catches and the modest increase in biomass, the exploitation rate fell to 10.7% in 2021/22 (Figure 27).

Model diagnostics and potential biases (from 2021/22 assessment model)

The length-frequency data input to the model (Figure 35 to Figure 38) is highly variable due in part to low sample sizes. Given this level of variability, the stock assessment model provides a reasonable fit to CPUE and length-frequency data (Figure 39 and Figure 40).

As shown in Figure 28, there has been a shifting bias through time in the stock assessment model CPUE estimates. This is unsurprising for a model of this complexity when fitted to a fishery like the Eastern Zone, which is comparatively small in production but large in spatial extent (hence has high variability) and for which only limited data is available. Notably recent estimates have a high degree of uncertainty partly due to the further reduction in data resulting from reduced catches.

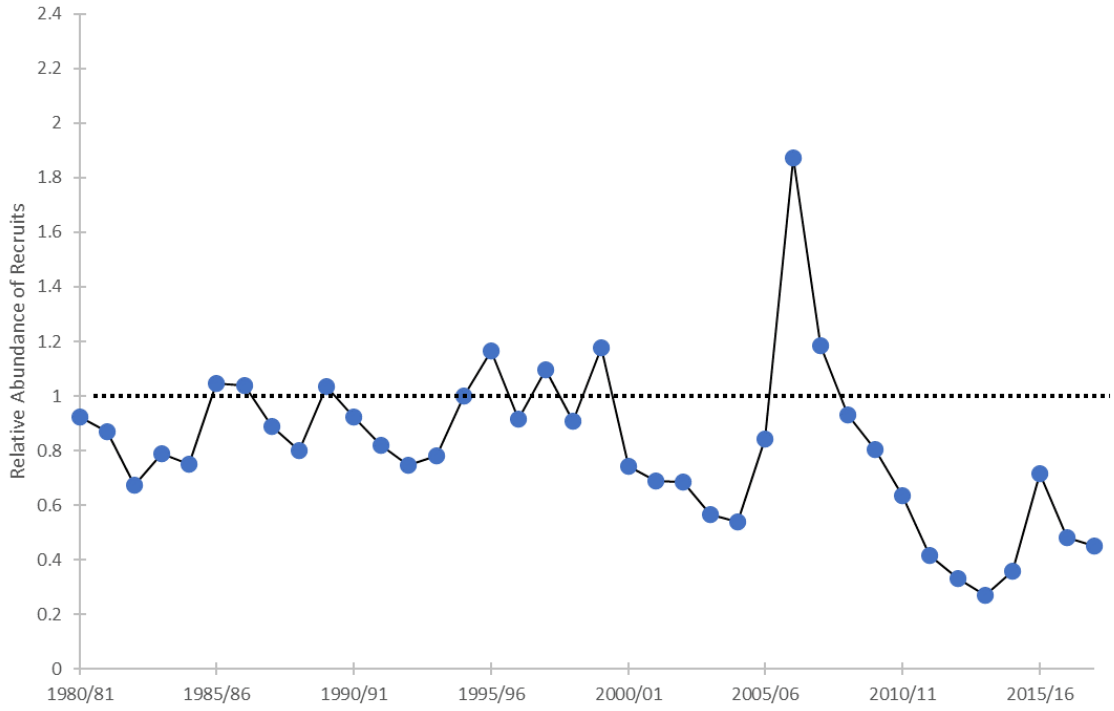

Figure 24: Relative number of recruits (to 60 mm in CL) in the Eastern Zone Fishery. These results are generated by the stock assessment model. The long-term average is indicated by the dotted black line. The most recent values are based on fewer observations and are therefore more likely to change in future stock assessments as more information about that year class becomes available.

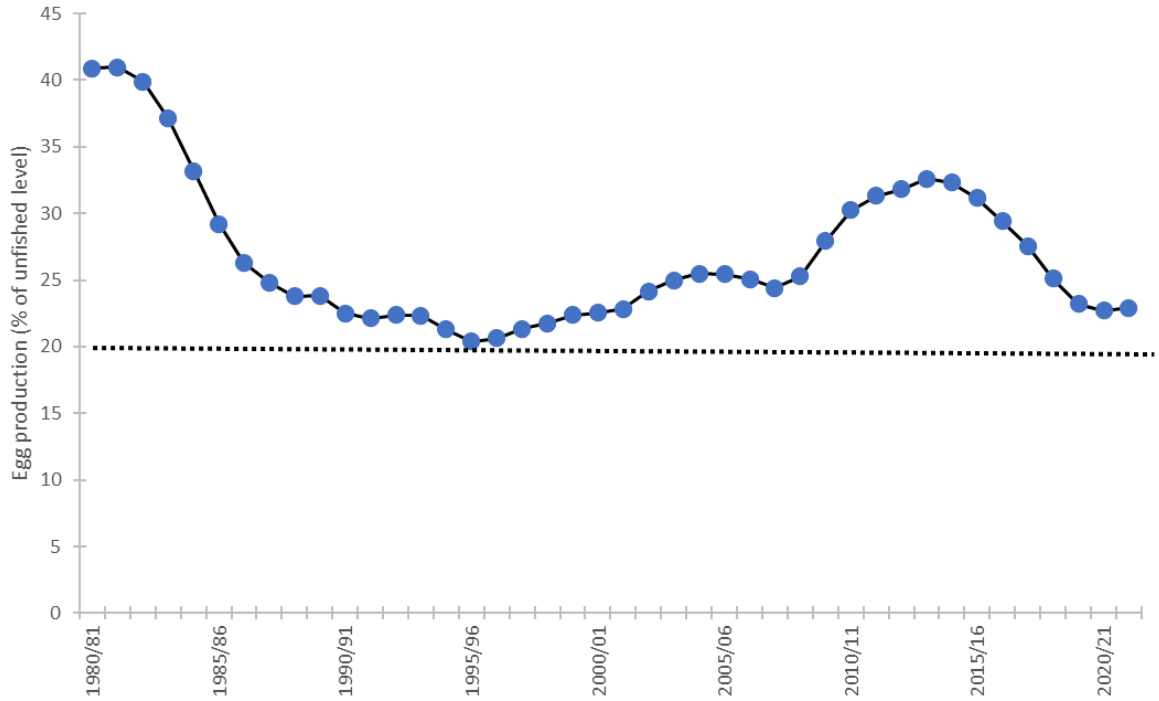

Figure 25: Model estimated level of egg production through time in the Eastern Zone fishery. The limit reference point (dotted line) is 20% of unfished levels.

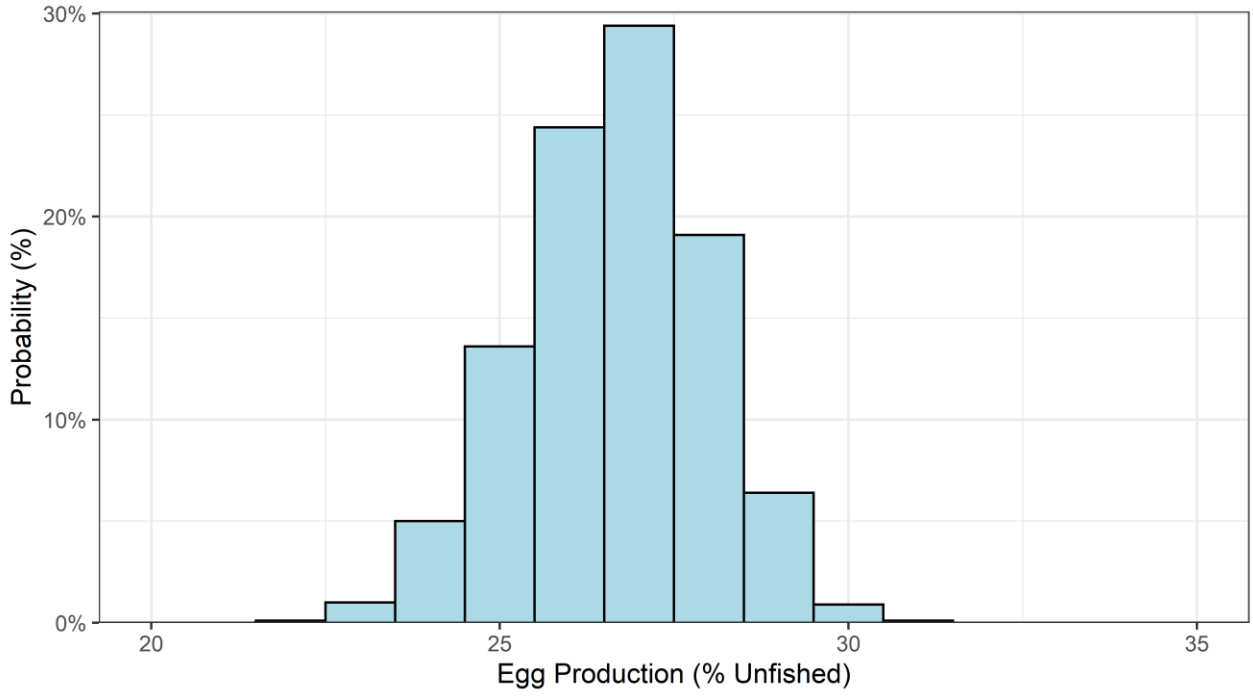

Figure 26: Probability distribution of model estimated egg production in 2022 compared to the unfished level of egg production in the Eastern Zone.

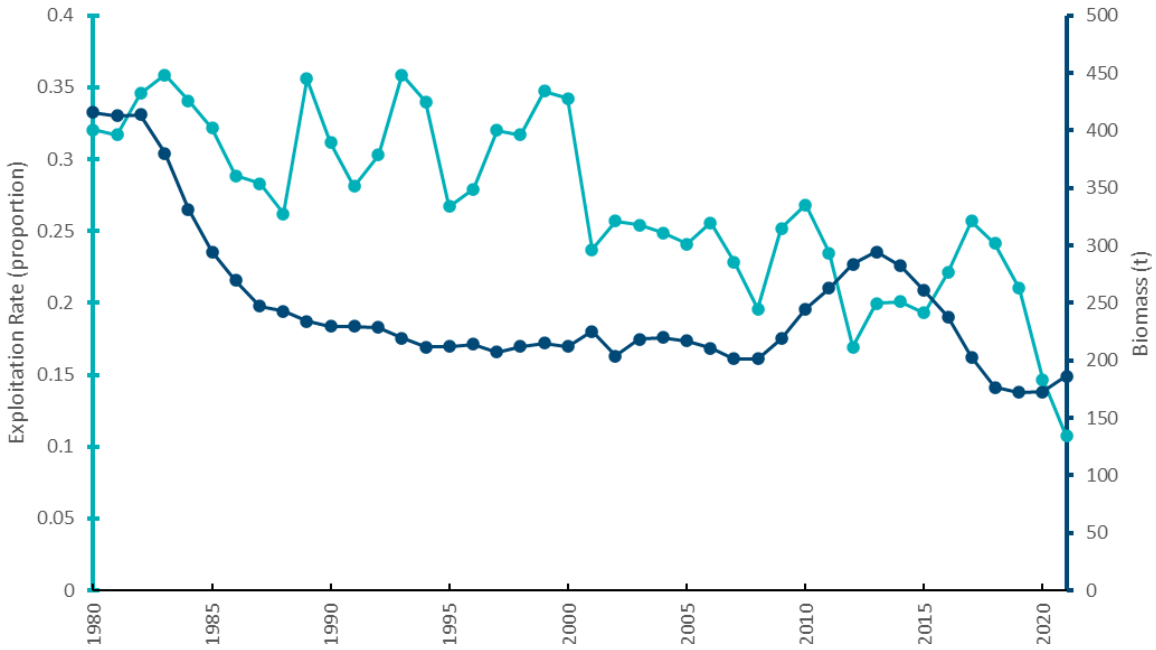

Figure 27: Model estimated levels of available biomass (dark blue) and associated fishing exploitation rates (light blue) in the Eastern Zone

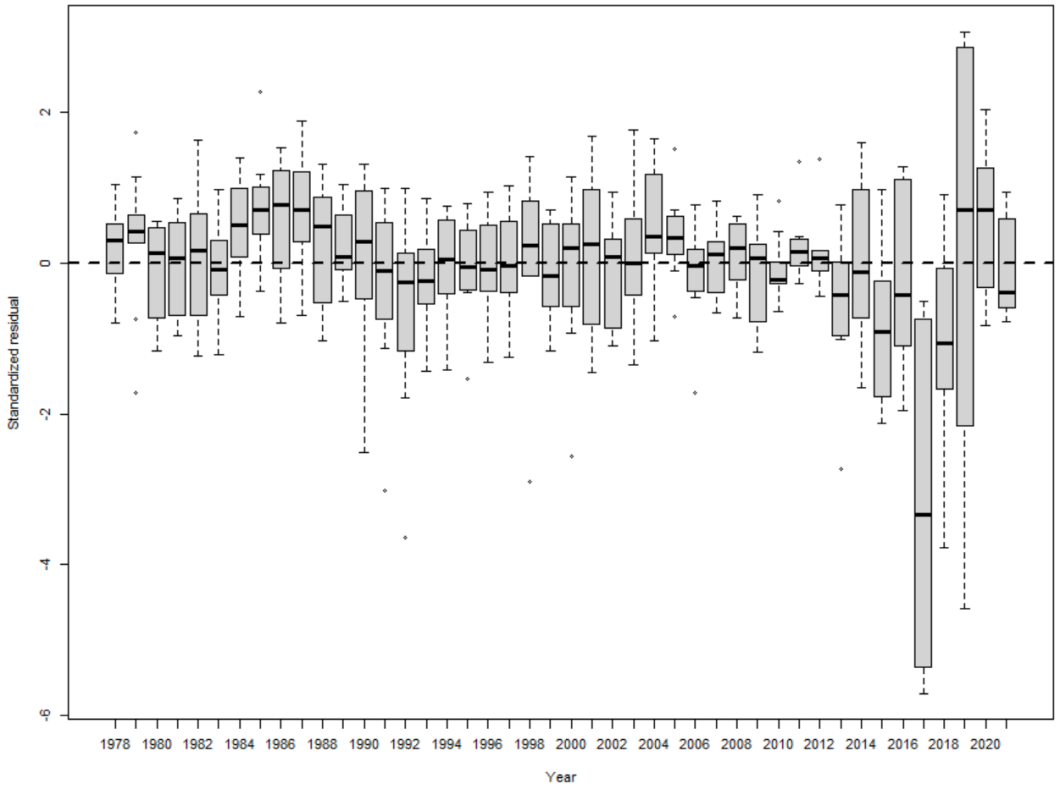

Figure 28: Standardized residual for CPUE in the Eastern Zone. Where values are positive, they indicate that the model is under-estimating CPUE and negative values indicate that the model is over-estimating CPUE.

4.4 APPLICATION OF THE HARVEST STRATEGY

The annual TACC is set on the basis of the response to the decision rules contained within the harvest strategy as described below.

Decision Rule	2023/24 Stock Indicator Level	Outcome
Part 1: Egg Production		
Is the model estimated egg production above the limit reference point of 20% of unfished levels?	The 2023/24 egg production level is likely to be above the 20% level based on the CPUE proxy and weight of evidence argument.	Decision rule has been met. Go to Part 2
Part 2: TACC Determination		
b. Is standardised CPUE in a higher band than the previous season?	CPUE increased from 0.48kg/pot-lift in 2022/23 to 0.60kg/pot-lift in 2023/24. This corresponds to a higher 0.60 -< 0.65 band.	The CPUE band has increased.
b. Is the 2023/24 PRI at or above the threshold level of 0.25 undersize/pot-lift?	The combined PRI was 0.02 in 2023/24. This is a significant reduction that is well below the threshold level.	The combined PRI is below the threshold level.
	RESULT	**The Eastern Zone remains in the same CPUE band (0.45-<0.50) with a TACC of 21t.**

Establishing the EZ TACC for 2025/26

A direct application of the decision rules in the harvest strategy specifies that the same 0.45-<0.50kg/pot-lift band is retained (in Step 1). This is the second year that the PRI is below the threshold which triggers the harvest control rule to be reviewed.

In summary:

- **The CPUE band remains at 0.45-<0.50 in Step 1.**
- **A TACC of 21t should be set.**
- **A review is required as PRI has been below the threshold in two consecutive years.**

5. METHODS

5.1 CATCH RATE STANDARDISATION

The stock assessment model uses standardised CPUE (Walker *et al.* 2012). All catch and effort data are obtained from mandatory logbook returns and are firstly checked for any errors before being entered into the Victorian Fisheries Authority rock lobster database. Prior to standardisation, the data are filtered to ensure that only data from fishers contributing returns in more than two separate fishing years and contributing 200 or more records are included in the CPUE standardisation. The CPUE is then standardised for each zone separately by adjusting for average long-term differences among the regions, depth ranges, fishing seasons, months, fishers and vessels. For standardisation, the regions are Portland, Warrnambool and Apollo Bay in the Western Zone, and Queenscliff, San Remo and Lakes Entrance in the Eastern Zone. The fishing depth ranges are <40 m and ≥40 m. Only interactions between region and year are now included, which permits yearly estimates of standardised CPUE by region.

It should be noted that the approach taken to create the overall standardised index for a zone calculates the predicted CPUE for each region in each year and weights these by their relative catches. Consequently, the standardised index contains trends due to spatial shifts in catch (at a region level) that are unrelated to biomass changes. For example, the increase in catch in Lakes Entrance in 2017/18 and 2018/19 (which has the highest CPUE out of the Eastern regions) had a small positive effect on CPUE.

5.2 PRE-RECRUIT INDEX

The pre-recruit index (PRI) provides an index of the abundance of undersize lobster in each zone. This is based on two data sources: observer-based records and fixed site data. These data sources have different characteristics and their spatial coverage varies over time. Hence the steps listed below are applied to calculate an index that is consistent across years and as representative as possible of undersize abundance. One key implication is that the observer component of the PRI is scaled to match the fixed site program. Consequently the magnitude of the index may not match that experienced by individual operators, however the same trends in undersize abundance should be observed.

1. Weighting of fixed sites

Western Zone: To obtain an overall undersize catch rate from the fixed sites, the average must be calculated. Each site corresponds to different areas of the fishery with different productivity and importance to the commercial fleet. To obtain a representative undersize index each site is therefore weighted by the productivity or importance of the area it represents. This is achieved by weighting each area according to the proportion of the overall commercial catch it provided between 2010 and 2015. For consistency this year range has not been updated since the PRI was first calculated.

Eastern Zone: Due to the limited regional coverage, each site is given the same weight. To ensure the sites contribute evenly they are normalised before calculating their combined mean and then scaled back to the overall regional mean.

2. Weighting of observer-based PRI

Western Zone: The spatial coverage of the observer data varies substantially from year to year. Consequently, simply computing the average would result in spatial shifts affecting the PRI. To address this, the same approach was taken as for the fixed sites whereby the data is divided into different spatial areas and combined, weighting by the average catch for 2010-2015 in these areas.

Eastern Zone: Spatial coverage in the Eastern zone is limited across all years and does not exhibit the same level of spatial variability as seen in the Western Zone. Hence a simple annual mean for undersize catch rates is calculated.

3. Scaling the observer-based PRI

The observer and fixed site components of the PRI have very different magnitudes due to the methods employed (including pots, fishing locations and times). Consequently, if they were combined by simple averaging the trend in the fixed site component of the PRI would dominate that in the observer-based PRI. To overcome this the observer-based PRI is scaled up to have the same magnitude as the fixed site survey index.

Threshold level

The PRI is compared against a threshold level. This level is based on a normal distribution fitted to a reference period from 2008/09 to 2020/21. The threshold level is set at the 40th percentile of this distribution. This means that if future PRI values are similar to those in the reference period, then twice in every 5 years the PRI would be below the threshold level and the harvest control rule would prevent a TACC increase (if this were permitted by the CPUE).

It is important to note that PRI in each year includes some of the age classes that contributed to the PRI in the previous year. Thus PRI changes gradually and there can be extended periods during which the PRI remains below the threshold (as has happened in recent years).

5.3 STOCK ASSESSMENT MODEL

The stock assessment uses a model that has been designed for rock lobster fisheries in Victoria, South Australia, and Tasmania. It was developed through CSIRO and a series of FRDC projects (Hobday and Punt 2001; Hobday and Punt 2009; Hobday *et al.* 2005). The model is length-structured and currently set up in Victoria to account for numbers of rock lobsters in 5-mm-carapace length-classes.

The model infers change and absolute levels of stock abundance from three principal data sources: (i) standardised CPUE, to which biomass is assumed to vary in direct proportion, (ii) catches in both weight and number, which provide a highly precise measure of mean weight of lobsters in the catch, and (iii) length-frequency data interpreted in combination with the length-transition matrices to yield estimates of mortality rate and absolute biomass.

Recruitment in the model is dependent on changes in mean size and size distribution of the catch from length-frequency data, and on changes in standardised CPUE, where, for example, a rise in CPUE and a decrease in mean size signals an increase in recruitment and visa-versa. For males and females separately, the model tracks, for each month, the number of rock lobsters in the population of size equal to or larger than 60 mm carapace length. The model also accounts for both natural mortality and fishing mortality.

Growth is modelled using length-transition matrices that specify the proportion of lobsters in each length category that grow into larger length classes during each summer and autumn moulting period. Growth in the model is sex specific, as is length-selectivity. Catchability by month is non-sex specific. The length-transition matrices were estimated using extensive tag-recovery data.

5.4 CONTINUAL IMPROVEMENT REPORT

Significant work was undertaken in previous years to support the development of the new management plan and harvest strategy. This management plan was formally adopted in 2024 and the associated work is

discussed in the previous assessment. Consequently, during 2024 less work on continual improvement was undertaken which is also commensurate with reduced resourcing due to the cessation of an annual application of the stock assessment model to the Eastern Zone. Work presented to the RLRAG during 2024 included:

- The first application of the new harvest control rule and consideration of the associated impacts. (RLRAG 41).
- A review of the length-weight relationship, in particular temporal and regional differences. This indicated small differences that were insufficient to warrant further investigation of a proposed project for collecting further length-weight data (RLRAG 42).
- Discussion of the possibility and benefits of commencing long term data collection of fleet characteristics to aid the calculation of a vessel efficiency factor (RLRAG 43).

Appendix 1: Rock Lobster Fishery Significant Events

Year	Licensing Season	Significant event
1934		Closed season female 1/6-30/11
1955		Sounders, radar and larger wells become available
1958		Closed season: female 1/6-31/10 (reduced), male 1/10-31/10 (introduced)
1959		Illegal to take females in berry, remove berry or take soft shelled crays
1961		Upgraded from cotton to nylon ropes
1968		Pot restrictions according to vessel length
1968		Limited entry to Rock Lobster Fishery and creation of Western and Eastern zones and 'Corridor'
1975		Bottom locked sounders
1980	1980-81	Colour sounders and sat nav
1982	1982-83	Western zone pot reductions + 20 % pot forfeiture on pot transfers
1985	1984-85	Creation of the 'Paddock'
1985	1985-86	5% pot forfeiture on pot transfers
1986	1986-87	Closed season male and female extended to 15/11
1987	1987-88	Closed season male extended to 1/9-15/11
1988	1988-89	GPS and GPS plotters
1990	1990-91	Introduction of escape gaps
1993	1992-93	Peak of giant crab
1996	1995-96	Rock lobster quota management discussions
2001	2001-02	Introduction of quota management rock lobster East and Western zones
2002	2002-03	Introduction of quota management Giant Crab Western zone
2002	2002-03	Introduction of marine protected areas Eastern Zone
2003	2003-04	Extension of open season 2 weeks into September and targeting of 'red' inshore lobsters
2003	2003-04	Extension of open season for males 2 weeks into September
2004	2004-05	Introduction of marine protected areas Western Zone
2004	2004-05	SARS epidemic results in beach price drop from over $40/kg to under $30/kg
2010	2010-11	November: Beach price reaches peak of $79/kg (Tas data)
2010	2010-11	December: Chinese export restrictions drop beach price to $40/kg (Tas data)
2017	2017-18	Victorian Rock Lobster Management Plan and harvest strategy introduced
2017	2017-18	Recreational lobster tagging and catch reporting is introduced
2019	2019-20	Beach price frequently exceeding $100/kg (Tas data)
2020	2019-20	COVID-19 drops beach price significantly in early 2020 and from November 2020 onwards
2020	2019-20	Introduction of VMS and electronic logbook reporting
2020	2020-Ongoing	Loss of market access to China results in dramatic beach price reduction
2023	2023-24	Additional significant TACC reduction in the Eastern Zone to 21t to facilitate rapid recovery following ongoing low recruitment.
2024	2024-Ongoing	Adoption of a new management plan with formalised targets, sectoral allocations and rebuilding timeframes.
